Abstract

I propose that the phenomenon of "small moment magnetism" observed in some heavy fermion compounds is the consequence of a *weak admixture* of ordered excited *magnetic* f-shell states in an essentially Kondo quenched ground state. The magnitude of the dynamically generated admixture determines the size of the magnetization.

Heavy fermion materials continue to be an extraordinarily rich source of puzzling collective behavior in condensed matter physics [1]. Several of these compounds exhibit magnetic order with two different overall trends. In most materials, the transition into the ordered state leads to the formation of an antiferromagnetically ordered moment, whose magnitude is comparable with the free ion value. However, in a few other compounds the magnetic state is characterized by a minute value of the ordered moment: UPt_3 ($\mu = 0.02\mu_B$) [2], URu_2Si_2 ($\mu = 0.04\mu_B$) [3], $CeRu_2Si_2$ ($\mu < 0.001\mu_B$) [4], UPd_3 ($\mu \sim 0.01\mu_B$) [5], $CeAl_3$ ($\mu \sim 0.05\mu_B$) [6], for example.

This peculiar magnetic state shows some other anomalous properties. In URu_2Si_2, application of an external magnetic field strongly suppresses the low temperature value of the moment while leaving T_N largely unaffected [7]. Such behavior is rather anomalous since, in a conventional magnet, these two quantities are expected to scale with each other. In all of the above cases, except URu_2Si_2, the transition into the ordered state does not lead to noticeable effects on thermodynamic or transport properties. In the case of URu_2Si_2, however, large jumps in the specific heat [8], the nonlinear susceptibility [9] and resistivity [10] are observed. It is not at all clear how the appearance of such a small order parameter can lead to these large jumps. Attempts to explain this behavior have usually involved some multi-spin operator as the principal order parameter [9,11]. However, recent neutron scattering experiments in a magnetic field seem to be inconsistent with a multi-spin order parameter and instead point to a second order phase transition into a state with magnetic dipolar order [7].

Since this is a trend found in a variety of compounds, any microscopic theory should satisfy two criteria: (1) It should explain the origin of the small scale governing the size of the moments and (2) one should not have to fine tune the bare parameters of the model in order to generate this small scale. I suggest that mixed valence is essential to the understanding of the small moment enigma. Recently, Barzykin and Gor'kov [12] have analyzed this possibility within a macroscopic Landau functional description. I will develop a microscopic description where it is essential that the lowest f-multiplets of each valence state are both degenerate. Most past studies of heavy-fermion magnetism have focused on an Anderson lattice model
